Peri-implant Tissue Measurement Terminologies in Health and Disease: A Critical Insight

Anil Akansha¹, Kharidhi L Vandana²

Abstract

The implantology field has been a center of interest for several clinicians, teachers, and students globally. Amidst these fast-moving tissues, the terminologies for peri-implant measurements and the standard concept of measurement guidelines remain obscure and compromised. Unfortunately, the pioneering implantologists have not made an adequate attempt to address the existing deficiencies in guidelines, terminologies, and measurements pertaining to peri-implant tissues in health and disease. There is a lack of consistency across definitions of peri-implant osteitis in the literature, and the diagnostic criteria are not clear. Most of the published strategies for peri-implant osteitis therapy are mainly based on treatments used for teeth with periodontitis. The required platform to diagnose, classify, treat and comprehensive terminologies are the need of the hour in the implant related world. Hence, an attempt is made in this paper to briefly address the peri-implant-related clinical measurements, peri-implant disease classification, and its treatment strategies.

Keywords: Peri-implant measurements, Peri-implant osteitis, Peri-implant osteitis therapy, Periodontitis.

Introduction

Implantology is growing tremendously in clinical practice and in the academic front. Various systems and techniques have been researched for better implant bone stability to benefit the patient at a faster pace. The implantology field has been a center of interest for several clinicians, teachers, and students globally. Amidst these fast-moving issues, the terminologies for peri-implant measurements and the standard concept of measurement guidelines remain obscure and compromised, especially the classification of peri-implant disease and its treatment strategies. Unfortunately, the pioneering implantologists have not made an adequate attempt to address the existing deficiencies in guidelines, terminologies, and measurements pertaining to peri-implant tissues in health and disease.

Hence, an attempt is made in this paper to briefly address the peri-implant-related clinical measurements, disease classification, and treatment strategies.

The peri-implant measurement nomenclature can be initiated with reference to the periodontal measurements. Some of the important terminologies derived from natural tooth, i.e., periodontal measurements are:

- Probing pocket depth (PPD) referred to as peri-implant probing depth (PIPD).¹
- Clinical attachment level (CAL) can be referred to as peri-implant bone level (PIBL).
- The term peri-implantitis disease can be replaced by peri-implant osteitis.²,³
- There is a lack of any standardized classification to differentiate the various degrees of peri-implantitis, which has led to the confusion in interpreting the results of studies evaluating the prevalence, treatment, and outcome of therapy. The classification based on CIST is modified and presented in Table 1.³,⁴,⁵–⁳²
- The features of PPD and PIPD are presented in Table 1.

Limitations of Probing Pocket Depth and Peri-implant Probing Depth

The gingival margin tissue²⁶ of natural tooth and mucosal margin tissue³³ has a tendency to recede due to bone loss. Therefore, they both are not useful as dependable measurements to appreciate changes from baseline to postoperatively. Hence, there is a need for dependable measurement which utilizes a fixed landmark on tooth [cementoenamel junction (CEJ)] and implant (implant shoulder for 1-stage nonsubmerged implant or its suprastructure) to the base of the probable depth which is CAL in natural tooth and peri-implant bone attachment level (PIBL) in implants.

Peri-implant Bone Attachment Level

- The implant counterpart of CAL in normal tooth can be named as PIBL.
- So, instead of CAL in natural tooth, the term peri-implant bone attachment level (PIBL) is appropriate. This can be measured from a fixed landmark point on the implant (e.g., implant shoulder for 1-stage nonsubmerged implant systems) or its suprastructure¹ to the bone level. As of now, there is a lack of...
Table 1: Features of probing pocket depth vs peri-implant probing depth

<table>
<thead>
<tr>
<th>Criteria</th>
<th>Sulcus depth/probing pocket depth</th>
<th>Peri-implant sulcus depth/peri-implant probing depth</th>
</tr>
</thead>
<tbody>
<tr>
<td>Definition</td>
<td>The distance from the soft tissue (gingival or alveolar mucosa) margin to the tip of the periodontal probe during usual periodontal diagnostic probing. The distance from the gingival margin to the location of the periodontal probe tip inserted for gentle probing at the attachment. The probing depth is the distance between the gingival margin and the depth of the probe tip penetration into the pocket.</td>
<td>It is the distance from mucosal marginal position to peri-implant sulcus/pocket depth.</td>
</tr>
<tr>
<td>Instruments used</td>
<td>Metallic instruments</td>
<td>It is possible to use the same type of metal probe around the implant; however, specifically designed titanium probes are manufactured. Softer flexible plastic probes can be used to prevent the damage to the implant surface. (Fig. 1)</td>
</tr>
<tr>
<td>Probing force</td>
<td>A light probing force is used (0.2–0.3 N) so that the tip of the probe will stop coronal to the bone level, at the apical extension of the barrier epithelium. The probing force of 0.75 N has been found to be well tolerated and accurate. Curve analysis of depth force patterns showed that a change in probing force had more impact on the depth reading in the peri-implant than in the periodontal situation.</td>
<td>A light probing force is used (0.2–0.3 N) so that the tip of the probe will stop coronal to the bone level, at the apical extension of the barrier epithelium. Peri-implant probing is more sensitive to force variation than periodontal probing. Curve analysis of depth force patterns showed that a change in probing force had more impact on the depth reading in the peri-implant than in the periodontal situation.</td>
</tr>
<tr>
<td>Probing depth (Fig. 2)</td>
<td>Clinical sulcus depth of &lt;3 mm and true pocket depth of &gt;3 mm are definitive of health and disease status of periodontium.</td>
<td>A light probing force is used (0.2–0.3 N) so that the tip of the probe will stop coronal to the bone level, at the apical extension of the barrier epithelium. The baseline PIPD varies depending on the level of implant placement. The changes in the PIPD need to be always compared with baseline sulcus depth for ascertaining disease state. Change in probing parameters over time is more important than initial findings, i.e., there is no normal sulcus depth around implant and it varies; hence a baseline probing should be done once the final restoration has been installed. A casual mention on implant sulcus depth is said to be around 2.5 mm to 4 (average). Clinical probing depth is higher around implants vs teeth. Probe tip penetrates closer to the bone level unlike natural tooth. This occurs even when the tissues are healthy, because of the lack of connective tissue fiber bundle embedded in the implant surface, which does not prevent the penetration of the tip. Fibers run a parallel course to the implant surfaces as observed by some investigators, and in some, fibers found to be running in different directions. However, perpendicular orientation of the fiber was also found in implants with porous surface. The connective tissue adhesion with implants has a poor mechanical resistance as compared to the natural tooth. This, combined with reduced cellularity and vascularity in the peri-implant connective tissue, may make them more susceptible to disease initiation and progression. Thus explaining the deeper penetration of probe tip. Peri-implant crevice is surgically created and is not developed as it is for natural tooth.</td>
</tr>
<tr>
<td>Fiber arrangement</td>
<td>The dentogingival collagen fibers are firmly inserted into the cementum and the bone and in a perpendicular or oblique direction, thus serving as a barrier to the epithelial migration and the impending bacterial invasion. Thus establishing a probing depth around the teeth.</td>
<td></td>

Contd...
specific nomenclature for several of implant-related clinical measurements.

- As with the natural tooth, the CAL is measurable due to the presence of the connective tissue between tooth and bone. However, this connective tissue is missing in relation to the peri-implant area as the peri-implant bone hugs the implant screw. Three landmarks:
  - Gingival margin
  - Cement–enamel junction
  - Base of the sulcus/pocket
  - The probing pocket depth is read out in relation to the gingival margin using the markings of the periodontal probe

- Histology
  - Higher proportion of lymphocytes, macrophages, and PMNs
  - Junctional epithelium attaches to the enamel surface via internal basal lamina and desmosomes along the entire length of junctional epithelium

- Influenсing factors:
  - Root morphology
  - Shape of the crown
  - Anatomic features like concave surfaces, anomalies, shape of cervical third, and position of furcation

- Instruments used for treatment
  - Metallic supra and subgingival scalers and curettes
  - Ultrasonic and sonic instruments

In contrast to the natural tooth, the CAL is measurable due to the presence of the connective tissue between tooth and bone. However, this connective tissue is missing in relation to the peri-implant area as the peri-implant bone hugs the implant screw. The histologic study in human biopsy specimens showed that the inflammatory infiltrate in peri-implantitis lesions is in direct contact with the alveolar bone and extends into marrow spaces. This differs from the periodontal lesion, in which the inflammatory infiltrate is separated from the bone by approx. 1 mm of noninflamed connective tissue.

Conflicts on Classification

Most of the published strategies for peri-implantitis therapy are mainly based on the treatments used for teeth with periodontitis.

- The extant treatment strategies for peri-implant diseases are based on the Cumulative Interceptive Supportive Therapy (CIST) protocol. The major drawback of this proposal is dependence...
on the implant pocket depth, which is found to be variable even in healthy status.

• There is a lack of any standardized classification to differentiate the various degrees of peri-implantitis, which has led to confusion in interpreting the results of studies evaluating the prevalence, treatment, and outcomes of therapy.

• Froum and Rosen⁴ proposed a classification for peri-implantitis based on the severity of the disease. A combination of bleeding on probing and/or suppuration, probing depth, and extent of radiographic bone loss around the implant were used to classify the severity of peri-implantitis into early, moderate, and advanced categories. Again, this classification considered pocket depth as a clinical parameter, and hence a modified treatment strategy⁵ based on the clinical, radiologic, and diagnostic criteria and the prognosis has been introduced for the first time (Table 2). The use of greater than or less than 2 mm of PIPD is eliminated as there is no specific normal PIPD/sulcus depth, which depends on the level of implant placement.⁶

**Controversial Nomenclature**

The nomenclature “peri-implantitis” appears to be a misnomer: the addition of the suffix “itis” is used to signify inflammation of living tissues, e.g., mucositis “itis”; the addition of “itis” to a nonliving implant remains highly questionable scientifically. The natural bone that integrates around the implant, peri-implant bone, is inflamed during the disease process. The obvious sign of osteitis is loss of bone appreciated radiographically. Hence, the term “peri-implant osteitis” is recommended instead of “peri-implantitis.”⁵

**Treatment Strategies**

The treatment of peri-implant infections comprises conservative (nonsurgical) and surgical approaches as suggested by Vandana (2015) and is presented in Table 3.

Primary goals of the treatment:

• Elimination of peri-implant mucosal inflammation.

• Cessation of peri-implant disease progression.

• Maintenance of functionality of implant with healthy peri-implant tissues.

• Regeneration of lost peri-implant tissues.

• Restoring peri-implant esthetics such as treatment of mucosal recession, inadequate width, and thickness of peri-implant mucosa.

Other terminologies which are of limited mention in literature and with minimum explanation:

• Early peri-implantitis, defined as the presence of an inflammatory lesion of infective etiology when osseointegration is being established and the implant is mechanically stable.

• Chronic implantitis, the slowly progressive form of the disease.

• Aggressive form of peri-implantitis, a rapidly progressive form of the disease.

• Necrotizing form of peri-implantitis.

• Early implantitis.

• Retrograde implantitis (Meffert, 1996): refers to the presence of a lesion at the apex of the implant. A condition known as retrograde peri-implantitis may also be associated with implant failure.

Retrograde implant failure may be due to bone microfractures caused by premature implant loading or overloading, other trauma, or occlusal factors. Implant failures from retrograde peri-implantitis are characterized by periapical radiographic bone loss without, at least initially, gingival inflammation. The distinction between implant failure due to infection with periodontal pathogens (infective failure) and implant failure associated with retrograde peri-implantitis (traumatic failure) is also reflected in the microflora.⁵

**Conclusion**

There is a lack of consistency across definitions of peri-implant osteitis in the literature, and the diagnostic criteria are not clear. Most of the published strategies for peri-implant osteitis therapy are mainly based on treatments used for teeth with periodontitis. The required platform to diagnose, classify, treat and comprehensive terminologies are the need of the hour in the implant related world. This attempt made by the authors to present these issues is first of its kind and may benefit the implantologists across the globe.
